ABSTRACT

Background: Intracranial migration of odontoid screws is a rare but serious complication of anterior odontoid screw fixation not often reported in literature by neurosurgeons. Here, we describe the second case in literature of intracranial migration of an odontoid screw.

Case Description: A 64-year-old neurologically intact patient with a type II odontoid fracture secondary to trauma underwent anterior odontoid screw fixation without any intraoperative complications. He tolerated the procedure well, and postoperative imaging demonstrated near anatomic correction of the fracture with satisfactory placement of the lag screw. Unfortunately, the patient was subsequently lost to follow up and he presented 7 months later for a routine outpatient computed tomography (CT) of the cervical spine, which demonstrated upward migration of the screw into the intracranial cavity abutting the medulla, with CT angiography of the neck also confirming the screw lying between the two vertebral arteries. Magnetic resonance imaging of the cervical spine also demonstrated the odontoid screw lying within close proximity to the ventral cervicomedullary junction, marginating the left vertebral artery. Subsequently, the patient was managed with removal of the odontoid screw and posterior cervical arthrodesis and instrumented fusion.

Conclusion: Our case demonstrates the rare but serious complication of intracranial odontoid screw migration, which we bring to the attention of the neurosurgical community. The recognition of risk factors for this complication and optimized management of this rare occurrence is important for surgeons to recognize.

Keywords: Anterior odontoid screw fixation, C2 odontoid screw, Postoperative intracranial migration

INTRODUCTION

Odontoid fractures are the most common cervical spine fractures with an occurrence of approximately 20% of all cervical fractures.5,11 Broadly speaking, odontoid fractures are divided into three categories, based on Anderson and d’Alonso classification: (1) type I: oblique fracture through the tip of the dens; (2) type II: fracture at the base of the dens, in the junction with the axis body; and (3) type III: fracture extending into the body of the axis, with or without the involvement of atlantoaxial joint.1,13 Of the three classes of odontoid fracture, type II is the most common, occurring approximately 65%–74% among elderly population.4,16
Treatment options for type II odontoid fractures can be conservative or surgical. Due to the patient discomfort and high risk of nonunion and mortality with conservative approaches in a subpopulation of patients, surgical stabilization is typically favored and is becoming the norm for this subpopulation.\cite{8,19} Among surgical techniques, the two widely practiced procedures are anterior odontoid screw fixation (AOSF) and posterior cervical instrumented fusion (PCIF). While each of these procedures has unique indications and contraindications, AOSF is preferred by some spine surgeons due to its minimally invasive nature, minimal blood loss, high fusion rate from 89% to 100%, quicker postoperative recovery with preservation of normal atlantoaxial rotation, and maximum postoperative cervical spine motion.\cite{10,19} However, this procedure is technically quite challenging with screw breakage, malposition, and loss of fixation as some of the many possible complications – hardware failure occurs generally in a delayed fashion and is often associated with pseudoarthrosis.

We present a rare case of a 64-year-old male who presented with a posttraumatic type II odontoid fracture which was managed through AOSF. A routine computed tomography (CT) scan of the cervical spine 7 months later demonstrated intracranial migration of the screw, with the patient undergoing subsequent removal of the screw and PCIF. To the best of our knowledge, intracranial migration of odontoid screws has only been described in literature once, making our case, the second reported case of upward migration of an odontoid screw. We provide a comprehensive review of literature demonstrating postoperative migration of anterior odontoid screws and discuss the current management that spine surgeons must face when dealing with this rare, yet critical, complication.

**CASE DESCRIPTION**

A 64-year-old male presented as an intoxicated pedestrian who was involved in a hit-and-run incident. Initial trauma workup demonstrated that the patient had sustained a type II odontoid fracture [Figure 1]. He subsequently underwent AOSF for this fracture, without any intraoperative complications. He tolerated the procedure well and postoperative imaging demonstrated near anatomic correction of the fracture with satisfactory placement of the lag screw [Figures 2 and 3]. Postoperatively, the patient was to attend physical therapy. Unfortunately, the patient was subsequently lost to follow up and he presented 7 months later for a routine outpatient CT of the cervical spine, which demonstrated upward migration of the screw into the intracranial cavity abutting the medulla [Figure 4], with CT angiography of the neck also demonstrating the screw lying between the two vertebral arteries [Figure 5]. The patient had also obtained a magnetic resonance imaging of the cervical spine which demonstrated the odontoid screw lying within close proximity to the ventral cervicomedullary junction, marginating the left vertebral artery [Figures 6 and 7]. Although he did not exhibit any neurological symptoms at this
time, given the migration of the screw, there was nonunion of the patient's fracture with increased risk of poor recovery and neurological deterioration. He was subsequently taken for an anterior removal of the odontoid screw with posterior open treatment and reduction, C1-4 posterolateral arthrodesis and instrumented fusion, and Brooks sublaminar wire placement of C1-2 posterior instrumentation [Figure 8]. He tolerated the procedure well and remained intact neurologically postoperatively.

DISCUSSION

Fractures of the C2 odontoid process are the most common cervical injury.\(^1,4\) These fractures lead to instability of the atlantoaxial joint which may result in cervical myelopathy and cervical spine compression. Management of these fractures can be done either conservatively by immobilizing the joint using a rigid or halo brace or surgically by AOSF or PCIF.\(^2,12\) However, nonsurgical management of these fractures is generally associated with poor outcomes and morbidity.\(^2\) While there is no current consensus on the best surgical treatment of type II odontoid fractures, AOSF has become popular among spine surgeons due to its minimal

invasive nature, immediate stabilization, preservation of the atlantoaxial joint movement, and high fusion rates.\cite{6} Since our patient was elderly and deemed healthy to undergo surgery, we chose to manage his type II odontoid fracture by performing an AOSF due to higher success rates of fusion with AOSF as compared to a stabilization by a cervical collar\cite{7} and for immediate and robust stability of the fracture without compromising the normal atlantoaxial rotation.\cite{8}

Screw loosening and migration are well-recognized complications of several spine procedures. There are some rare occurrences reported in literature.\cite{9,10,12,14,15,20} Moreover, in a review of multiple series of AOSF by Subach \textit{et al.}, the authors reported only 2 of 252 cases with screw migration, of which only one patient exhibited neurological symptoms and required screw removal.\cite{16} Among the cases reporting odontoid screw migration, most have described delayed esophageal or pharyngeal perforation which are summarized in Table 1.\cite{3,10,12} Lee \textit{et al.} reported migration of a lag screw through the pharynx 3 years after AOSF.\cite{10} Leitner \textit{et al.} reported a 78-year-old man who safely excreted a screw 8 years after implantation due to esophageal perforation and migration to the gastrointestinal tract.\cite{17} In an interesting case reported by Simonin \textit{et al.}, an odontoid screw migrated upward over a decade after AOSF and caused progressive quadriaparesis in a patient with rheumatoid arthritis.\cite{18} Radiographical evidence revealed compression of the medulla oblongata without intracranial migration of the screw, which was caused by pseudarthrosis of the fracture and partly due to erosion of the C1-2 facet joints with vertical translation.\cite{19} Reports of screw and plate loosening postcervical spine fusion found local infection and inadequate perioperative positioning of the patient as contributing factors that may potentially influence screw loosening and migration post-AOSF.\cite{3,16} Other common factors causing screw loosening and migration post-AOSF are abnormal anatomy (subaxial cervical spondylosis, barrel chest, short neck, and severe thoracic kyphosis), pathologic fracture, rheumatoid arthritis, and incompetent transverse atlantal ligament.\cite{13}

There has been some consideration in literature evaluating two-screw fixation versus single screw fixation. Jenkins \textit{et al.} demonstrated that in a series of 42 consecutive patients with odontoid screw placement, there was no significant difference in the successful union rates between one and two-screw fixation techniques (fusion was found to be 81% and 85%, respectively).\cite{20} Moreover, Sasso \textit{et al.} showed that the two-screw fixation technique did provide an increased stiffness in extension loading, with no significant difference in the biomechanical fixation rate between one- and two-screw fixation methods. Thus, we did not find it necessary to perform a two-screw fixation in our patient.

Postoperative anterior or posterior migration of odontoid screws is rarely reported in literature, being reported in literature only three times [Table 1]. Our patient sustained a posttraumatic type II odontoid fracture which was initially managed with AOSF with near anatomic correction of the fracture. Follow-up imaging nearly 7 months later demonstrated upward migration of the odontoid screw, which necessitated screw removal with PCIF and instrumented fusion.

To rectify the fixation and nonfusion of the fracture, we performed a PCIF and C1-C4 posterolateral arthrodesis and instrumented fusion following anterior screw removal. While PCIF is typically done to fuse C1-C2, we extended the fusion from C1-C4 to provide additional robustness to the fusion given that our patient was elderly and that his fracture still showed significant nonfusion in spite of 7-month post-AOSF.

CONCLUSION

Intracranial migration of odontoid screws is a rare but serious complication of AOSF. Here, we report the second case in literature of intracranial migration of an odontoid screw in a neurologically intact patient, managed with subsequent removal and PCIF. Our case demonstrates the rare but serious complication of intracranial odontoid screw migration, which we bring to the attention of the neurosurgical community.
